From RCTs to Secondary Data

- RCTs are the gold standard of causal inference: In an RCT, the treatment is randomized and hence uncorrelated with any confounding factors, i.e., $cov(X,\epsilon)=0$
- In practice, however, it can be challenging to implement a perfect RCT.
 - Crossover and spillover effects;
 - Ostly in terms of time and money
- Therefore, we may want to exploit causal effects from existing secondary data. Besides the **instrumental variable** method, we can also investigate **natural experiments**.

Regression Discontinuity Design

Implementation of RDD

Comparison: RCT & Natural Experiment

i Natural Experiment

A **natural experiment** is an event in which individuals are exposed to the experimental conditions that are determined by **nature** or **exogenous factors beyond researchers' control**. The process governing the exposures arguably **resembles randomized experiments**.

RCT

- Assignment of treatment is randomized by us
- Ireatment is under control by us
- Primary data

Natural Experiment

- Assignment of treatment is randomized by nature
- 2 Treatment is not controlled by us

Implementation of RDD

What is an RDD

 A regression discontinuity design (RDD) is a natural-experimental design that aims to determine the causal effects of interventions by identifying a cutoff around which an intervention is as if randomized across individuals.

Figure 1: Visual illustration of RDD

▲ロ ▶ ▲周 ▶ ▲ 国 ▶ ▲ 国 ▶ ● の Q @

Motivating Example

Business objective: What is the causal effect of receiving a Master's degree with Distinction versus Merit on students' future salary?

• Can we run the following simple linear regression and obtain the causal effects?

$$Salary_i = \alpha + \beta Distinction_i + \epsilon_i$$

- Can we use RCT?
- Can we use instrumental variables?

A Natural Experiment in the UK

- In the UK Education system, students receiving 70% or above final average grades will receive Distinction while students below 70% will receive Merit.
- The above setting gives us a nice natural experiment:
 - Students may improve their average grades from 60% to 69% by working harder, but they cannot perfectly control their average grades around the cutoff, say from 69.9% to 70%.

Why RDD Gives Causal Effects?

- For students just above 70%, to measure the treatment effects of receiving Distinction, we would need their *counterfactual salaries if they had not received Distinction*.
- At the same time, because the "running variable" **controlled** by the individuals **around the cutoff point**, it's as if the treatment was randomized near the cutoff. Thus, individuals near the cutoff should be very similar, such that there should be no systematic differences across the treatment and control group.
 - Similar to RCT, we overcome the fundamental problem of causal inference using students just below 70 as the control group.
- All else being equal, a sudden change in the outcome variable at the cutoff can only be attributed to the treatment effect.

Regression Discontinuity Design

▲ロ ▶ ▲周 ▶ ▲ 国 ▶ ▲ 国 ▶ ● の Q @

When Can We Use an RDD

- An RDD design arises when treatment is assigned based on whether an underlying **continuous variable** crosses a cutoff.
 - The continuous variable is often referred to as the running variable.
- \bullet AND the characteristic cannot be perfectly manipulated by individuals
 - We should only focus on individuals close to the cutoff point.

Exercise: eBay endorses sellers with 10,000 orders as Gold Seller. Can we use RDD to identify the causal effect of receiving Gold Seller endorsement on seller sales?

Section 3

Implementation of RDD

Regression Discontinuity Design

▲□▶ ▲□▶ ▲□▶ ▲□▶ ■ ● ●

Step 1: Select Sample of Analysis

- Determine the bandwidth above and below the cutoff and select the subset of individuals within the bandwidth
 - $\bullet\,$ e.g., if we choose a bandwidth of 0.5, we need to filter out students with average scores between 69.5 and 70.5
- We face a trade-off when selecting the bandwidth: If we choose a smaller bandwidth around the cut-off
 - Pros: Individuals should be more similar around the cutoff, thus it is more likely the control group and treatment group are "as-if randomized", thus higher internal validity.
 - Cons: We have a smaller subset of subjects which may not be representative of remaining individuals, thus lower external validity; We have a smaller sample size due to fewer individuals selected
- In practice, there is no specific rule how to determine the bandwidth. We need to run a set of different bandwidths as **robustness checks**.

Regression Discontinuity Design

Implementation of RDD

▲□▶ ▲□▶ ▲□▶ ▲□▶ □ のQ@

Step 2: Examine Continuity of Observed Characteristics

- ② Examine if other characteristics of the treatment group and control group are continuous at the cut-off point.
 - The idea is similar to "randomization check" in an RCT.

▲□▶ ▲□▶ ▲□▶ ▲□▶ ■ ●の00

Step 3: Data Analysis

O Regress the outcome variable on the treatment indicator to obtain the causal effect.

 $Y_i = \beta_0 + \beta_1 Treated + \epsilon_i$

- *Treated* is a binary variable for whether or not the running variable is above the cutoff.
- Sometimes, we may also want to control the running variable in the regression to mitigate its confounding effects.

The Causal Effect of Distinction on Salary

```
    Generate a synthetic dataset
```

```
pacman::p_load(dplyr,fixest,modelsummary)
 1
    n <- 1000 # 1000 individuals
 2
    set.seed(888)
3
    score<-runif(n,61,75) # generate scores between 61 and 75</pre>
4
    experience <- runif (n,0,3) # generate work experience between 0 and 3
5
6
    salary<-30000+ 2000*(score>=70) + # causal effect is 2000
7
      500 * \text{score} + 400 * \text{experience} + \text{rnorm}(n, 0, 800)
8
9
    data rdd <- data.frame(ID = 1:n.</pre>
10
                              score = score,
11
                              experience = experience,
12
                              salary = salary)
13
```

• Generate the treatment indicator, Distinction, in the dataset using dplyr

Natural	Experiment
000	

▲□▶ ▲□▶ ▲□▶ ▲□▶ □ のQ@

Linear Regression Analyses

• Run a linear regression: salary ~ Distinction

	(1)
(Intercept)	63 306.835***
	(57.722)
Distinction	5533.565***
	(94.638)
Num.Obs.	1000
R2	0.774
+ n < 0.1 * n	< 0.05 ** n < 0.01 *** n < 0.001

• The result suggests that Distinction can increase the salary by 5.5k, which is far from the true causal effect.

Regression Discontinuity Design

▲ロ ▶ ▲周 ▶ ▲ 国 ▶ ▲ 国 ▶ ● の Q @

RDD Analysis

- \bullet Step 1: Select a bandwidth around the cutoff, between 68% to 72%
- Step 2: Examine discontinuity of other variables (randomization check).
- Step 3: Run the linear regression on the smaller sample.

	(1)
(Intercept)	65 201.101***
	(81.291)
Distinction	2898.285 ***
	(110.725)
Num.Obs.	282
R2	0.710
+ p < 0.1, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$	

• Let's try other bandwidths on the Quarto document. As we tighten the bandwidth, what do you find?

000	

Regression Discontinuity in Time

- A natural experiment occurred on a day affecting all customers, we can then implement a **Regression Discontinuity in Time design (RDiT)** as follows
 - The running variable is time; the cutoff is the day on which the natural experiment took place

$$Y_{it} = \alpha + \beta_1 Post_{it} + \mu_{it}$$

- The underlying assumption for RDiT is that, the pre-treatment outcomes before the natural experiment are good counterfactuals for the post-treatment outcomes if the natural experiment had not happened.
 - For the underlying assumption to hold, we need to take a short time window before and after the natural experiment, e.g., 7 days, 14 days, or 30 days.
- The coefficient β_1 then measures the changes in the outcome variable before and after the natural experiment.
